Abstract

Rare earth elements (REEs) are an important group of elements both geologically and economically. The ability of hydrothermal fluids to mobilize REEs in natural, ore-forming environments depends on the chemical composition and the presence of suitable ligands such as chloride and fluoride. Here, we use molecular dynamics (MD) simulations to study the molecular structure and thermodynamic stability of La³⁺ species in Cl-bearing hydrothermal fluids. We develop a new polarizable force field for this system optimized by reference to density functional theory (DFT) calculations. The structural and thermodynamic data obtained with the new potential using the well-tempered metadynamics (WMetaD) technique reproduce experimental and *ab initio* MD simulation data well. Polarization effects are shown to be essential for predicting realistic association and stability constants, which was not achieved with simpler non-polarizable interaction potentials. Simulations with different box sizes indicate that the effects of simulation box sizes on calculated thermodynamic quantities are almost negligible at high temperatures.

importance in economic developments and potential of their supplies being at risk [1, 2], they have been classified as critical elements by the U.S. Geological Survey (USGS).

Hydrothermal processes control the mineralogy and grade distribution of several important REE

deposits, such as Gallinas Mountain in New Mexico [3] or Thor Lake in Canada [4]. The mobility of elements in hydrothermal fluids is primarily controlled by the chemical composition and speciation, which have been shown to be controlled by temperature and pressure [5]. Commonly formed REE complexes include carbonates, sulfates, fluorides and chlorides [6, 7]. Therefore, accurate knowledge 11 of the speciation of REEs in dilute to concentrated hydrothermal brines is necessary to improve 12 existing geochemical models and to complement existing mineral recovery and extraction processes. Lanthanum (La), which is classified as a light rare earth element (LREE), is generally enriched by 14 hydrothermal processes that form primary ore deposits. Several minerals like bastnasite, monazite, 15 zircon and apatite are important sources of REEs in such deposits [8]. Although LREEs form 16 stronger complexes with F⁻ with increasing temperature, Cl⁻ is considered to be the main transport 17 ligand of LREEs mainly because of its much higher availability in hydrothermal fluids [9]. Several experimental and theoretical studies have been conducted to determine the properties of La³⁺ aqua 19 and chloride complexes at room temperature (Table 1 in Guan et al. [9]). Experimental and 20 molecular dynamics (MD) simulation studies [10, 11, 12, 13, 14, 15, 16, 17] have shown that the hydration structure of La³⁺ at room temperature is a tricapped trigonal prism with nine water 22 molecules. Weak chloride complexation was found by Raman spectroscopy in LaCl₃ solutions with a solute concentration above 0.1 mol/kg [18], which was confirmed by AIMD simulations [19]. Petit et 24 al. [20] used a combination of pair potential-based MD and AIMD simulations and found an average configuration of La(H₂O)₈Cl₂⁻ in concentrated 14 mol/kg solutions. However, fully hydrated La³⁺ complexes were seen in 1 mol/kg solutions [17]. 27

Although aqueous lanthanum chloride solutions have been well studied at room temperature [17, 20, 19, 18], studies targeting hydrothermal temperatures and pressures are quite scarce in available literature. In the absence of experiments at high temperatures, earlier studies relied on extrapolations of room temperature data using a species-based equation of state (EOS), such as the Helgeson- Kirkham-Flowers (HKF) model [21]. Haas et al. [22] fitted a set of parameters for the HKF model at 25 °C, 1 bar. Mayanovic et al. [23] performed in situ X-ray absorption spectroscopy (XAS) of La³⁺ in Cl-bearing solutions up to 500 °C. They predicted a gradual increase in chloride complexation from zero at 25 °C to 3.1 at 500 °C. Migdisov et al. [24] performed high-temperature solubility experiments and published a set of HKF parameters that can be used up to 300 °C. As

far as computational studies are concerned, Guan et al. [9] is the only study available in literature.

38 They performed AIMD simulations up to 500 °C and reported speciation and association constants

in a wide range of temperatures, pressures and concentrations.

As the forces between atoms in AIMD simulations are calculated by electronic structure methods,
usually within DFT, such simulations require extremely large computational resources. Parameterized force fields are much more efficient and can overcome some of the shortcomings of AIMD while
still providing sufficient geochemical insights into fluid properties at hydrothermal conditions [25].
However, an accurate description of ionic and molecular interactions requires an analytical model
with sufficient chemical complexity. The explicit account of polarizability becomes particularly
important when dealing with highly charged ions having high polarization power in concentrated
solutions [26]. Many different polarizable force fields exist, each having a different representation of
polarizability [27, 28, 29], but none of them for the system and the thermodynamic conditions of
interest here.

In this paper, we fit an *ab initio*-based polarizable ion model (PIM) for the LaCl₃-H₂O system.
We use the new potential to study the speciation of La³⁺ and derive association constants of different
La-Cl complexes in dilute to concentrated brines at two different hydrothermal conditions. To
understand the importance of ionic polarizability, a comparative study is performed with a nonpolarizable pair potential [12]. The results are also compared to available AIMD and experimental
data, where available.

56 2. Methods

57 2.1. Polarizable ion model

The PIM describes the interactions between the charged particles of the system and has been used in previous studies [26, 30, 31], so we only summarize its functional form here. The total potential energy V_{total} of the system comprises four terms:

$$V_{total} = V_{charge} + V_{disp} + V_{rep} + V_{pol} \tag{1}$$

The V_{charge} term is calculated between ion pairs I and J from Coulomb's law

$$V_{charge} = \sum_{I,J} \frac{q_I q_J}{r_{IJ}} \tag{2}$$

where q_I, q_J are the charges of ions I and J and r_{IJ} is the distance between the ions. Ions are treated as rigid particles with fixed formal charges of +3 for La and -1 for Cl. The V_{disp} term

includes contributions from the dipole-dipole and dipole-quadrupole dispersion interactions:

$$V_{disp} = -\sum_{I,J>I} \left(f_6^{IJ}(r_{IJ}) \frac{C_6^{IJ}}{r_{IJ}^6} + f_8^{IJ}(r_{IJ}) \frac{C_8^{IJ}}{r_{IJ}^8} \right)$$
(3)

represented by the dispersion parameters C_6^{IJ} and C_8^{IJ} . Short range corrections to these interactions are described using Tang-Toennies functions $f_n^{IJ}(r_{IJ})$, which are of the form [32]

$$f_n^{IJ}(r_{IJ}) = 1 - c_n^{IJ} e^{-b_n^{IJ} r_{IJ}} \sum_{k=0}^m \frac{(b_n^{IJ} r_{IJ})^k}{k!}$$
 (4)

with m=6 for f_6^{IJ} and m=8 for f_8^{IJ} . Further, we set $c_6^{IJ}=c_8^{IJ}=1$ and $b_6^{IJ}=b_8^{IJ}=b_{disp}^{IJ}$.

The V_{rep} term accounts for the short range repulsion and is modeled by an exponential function with two parameters A^{IJ} and B^{IJ} as

$$V_{rep} = \sum_{I,I} A^{IJ} e^{-B^{IJ} r_{IJ}} \tag{5}$$

Finally, the polarization energy V_{pol} many-body electrostatic effects are described by the induced dipole $(\vec{\mu_I})$ terms. These are treated as additional degrees of freedom and obtained at each MD step by minimizing the polarization energy,

$$V_{pol} = \sum_{I} \frac{|\vec{\mu_I}|^2}{2\alpha^I} + \sum_{I,J} \left(\sum_{\alpha} \mu_{\alpha}^I T_{IJ}^{\alpha} q^J f_{pol}^{JI}(r_{IJ}) - \sum_{\alpha} q^I T_{IJ}^{\alpha} \mu_{\alpha}^J f_{pol}^{IJ}(r_{IJ}) - \sum_{\alpha\beta} \mu_{\alpha}^I T_{IJ}^{\alpha\beta} \mu_{\beta}^J \right)$$

$$(6)$$

x, y, z are the Cartesian coordinates. For the short-range corrections in V_{pol} , the sum in Equation 4 has m=4.

The solvent water molecules are described by the polarizable model described by Dang and Chang (DC) [29], which is compatible with PIM. DC water is a rigid 4-site rigid model, with an additional virtual site M along the symmetry axis of the molecule, which carries a negative partial charge and the induced dipole. The short range repulsion and dispersion interactions are described by Lennard-Jones (LJ) interaction on the oxygen atom only. The parameters of the DC model are summarized in Table 1. The functional form of the water potential is included in the SI. This model has been shown to correctly reproduce the trends in several thermophysical properties of bulk water from ambient to high temperature conditions [34].

where α^I is the ion polarizability, T_{IJ}^{α} and $T_{IJ}^{\alpha\beta}$ are multipole interaction tensors [33, 31] and $\alpha, \beta =$

2.2. Potential parameter optimization

103

104

105

106

The PIM potential parameters are determined sequentially. First, we derive the ionic polarizability (α^I in Equation 6) of La³⁺ and Cl⁻ ions. For La³⁺, DFT calculations are done with an isolated gas phase cation. The dipole induced on the cation by an electric field perturbation is analyzed by constructing maximally localized Wannier functions (MLWF) using the method by Molina et al.[30]. Since the effect of the coordination environment on the polarizability of anions is significant [31, 30], α^I of Cl⁻ ion is determined from analogous simulations of the solvated anion with box #3 in Table 2.

To determine the other adjustable potential parameters, the LaCl₃-H₂O system is split into 3 different subsystems: crystalline LaCl₃ to determine the La-La, La-Cl and Cl-Cl potential parameters, hydrated La³⁺ in liquid water to determine the La-O potential parameters and hydrated Cl⁻ in liquid water to determine the Cl-O potential parameters, both at 773 K, 5 kbar. The simulation boxes used for simulations of the individual subsystems are listed in Table 2 (boxes #1 to #3). AIMD simulations are performed for each of the subsystems with the PBE exchange and correlation (XC) functional [35] to generate structural configurations that are used as training set for the subsequent dipole and force fitting. For each configuration, MLWFs and atomic forces are computed. MLWFs are used to calculate the dispersion interaction terms (C_6^{IJ} and C_8^{IJ} in Equation 3) and ionic or molecular dipole moments. More technical details about the DFT-related and AIMD simulations and derived properties are given in the SI.

In a next step, the DFT-derived dipole moments are used to determine the short-range damping parameters of V_{pol} , b_{pol}^{IJ} and c_{pol}^{IJ} , using a dipole fitting approach [26, 36]. They are optimized to minimize the difference between dipole moments calculated from PIM and those obtained from DFT for the different training configurations:

$$\chi_{\mu}^{2} = \frac{1}{N_{conf}N_{atom}} \sum_{conf} \sum_{atom} \frac{|\vec{\mu}^{PIM} - \vec{\mu}^{DFT}|^{2}}{|\vec{\mu}^{DFT}|^{2}}$$
 (7)

where N_{conf} is the number of configurations in training set, N_{atom} is the number of atoms in each snapshot, $\vec{\mu}^{PIM}$ are the dipole moments obtained from PIM and $\vec{\mu}^{DFT}$ are the reference dipole

Table 2: Details of simulation boxes

box	system	edge lengths (Å)	density (g/cm^3)	molality (mol/kg)
#1	32 LaCl ₃ (crystal)	26.1332×15.0880×8.7432	3.77	-
#2	$84 \text{ H}_2\text{O}, 1 \text{ La}^{3+}$	14.2784	0.87	0.661
#3	84 H ₂ O, 1 Cl ⁻	14.2784	0.87	0.661
#4	$227 \text{ H}_2\text{O}, 1 \text{ La}^{3+}, 3 \text{ Cl}^{-}$	20.0	0.90	0.734
#5	$55 \text{ H}_2\text{O}, 1 \text{ La}^{3+}, 3 \text{ Cl}^-$	12.57	1.03	3.02
#6	$55 \text{ H}_2\text{O}, 1 \text{ La}^{3+}, 3 \text{ Cl}^-$	12.24	1.11	3.02
#7	$339 \text{ H}_2\text{O}, 1 \text{ La}^{3+}, 3 \text{ Cl}^{-}$	22.0	1.05	0.495

moments obtained from MLWFs. χ^2 is the relative mean square error (MSE).

Finally, the parameters of the short-range repulsion term (V_{rep}) and b_{disp}^{IJ} in V_{disp} are optimized following a similar procedure [26, 36] by fitting the forces calculated from PIM to those obtained from DFT:

$$\chi_F^2 = \frac{1}{N_{conf} N_{atom}} \sum_{conf} \sum_{atom} \frac{|\vec{F}^{PIM} - \vec{F}^{DFT}|^2}{|\vec{F}^{DFT}|^2}$$
 (8)

 \vec{F}^{PIM} are the atomic forces obtained from PIM and \vec{F}^{DFT} are the reference atomic forces obtained from DFT. b_{disp}^{IJ} are set equal to B^{IJ} for La-La, La-Cl and Cl-Cl interactions because they are found to be very close to each other. For Cl-O interactions, b_{disp}^{IJ} is taken as 0, consistent with Tazi et al.[26].

2.3. MD simulations

110

111

112

118

119

120

122

123

124

125

The fitted PIM potential is used to investigate the speciation and association constants of La-Cl complexes at 773 K and 5 kbar. The simulation boxes used to study speciation and thermodynamics are compiled in Table 2 (boxes #4 to #7). The edge lengths of the boxes are adjusted to match the densities obtained from EOS in Driesner et al. [37]. To prepare those boxes, first a box containing only water molecules is equilibrated at a density of $\sim 0.8 \,\mathrm{g/cm^3}$ with the SPC/E water model [38]. Boxes #4 and #7 are prepared by replacing some of the water molecules with a geometry-optimized LaCl₃ molecule.

MD simulations are performed in the NVT ensemble, that is, with a constant number of particles, N, volume, V and temperature, T, and with a time step of 0.5 fs. After initial equilibration, the

simulations are run for approximately 5 ns. To compare the fitted PIM potential against available

non-polarizable force fields, MD simulations are carried out with the same boxes using the pair 128 potential reported in Migliorati et al. [12] and Smith and Dang [39], referred to as N-POL in 129 the following. Details of the N-POL potential are described in Table S2. These potentials have 130 been shown to accurately predict the structural and thermodynamic properties of aqueous La³⁺ 131 at ambient conditions [12, 40]. To check the transferability of the PIM potential to subcritical 132 conditions, additional MD simulations are performed at 473 K and 400 bar. This temperature and 133 pressure are chosen to ensure solvent densities similar to the training set and to facilitate direct 134 comparison with AIMD data from Guan et al. [9]. 135

Structural analysis of the MD trajectories is done by computing partial radial distribution functions, $g_{IJ}(r)$, for different pairs of species I and J using the TRAVIS code [41]

where dn_r^{IJ} is a function calculating the number of particles of type J within a shell of thickness

136

150

151

153

$$g_{IJ}(r) = \left\langle \frac{dn_r^{IJ}}{4\pi r^2 \rho_J dr} \right\rangle \tag{9}$$

dr at a distance r from a particle of type I. ρ_J is the number density (N_J/V) of species J. The angular brackets denote ensemble average over the entire trajectory. Coordination numbers (CN) are calculated by counting the number of particles up to the first minimum of the respective $g_{IJ}(r)$. In order to calculate the association constants of different La-Cl complexes, well-tempered metadynamics (WMetaD) [42, 43] simulations are performed in the NVT ensemble for ~ 6 ns. Hills of height 1 kJ/mol and width 0.02 are deposited every 10² timesteps to get a good sampling of the associated and dissociated states within a reasonable simulation time. To allow a direct comparison with the AIMD data from Guan et al. [9] at their studied conditions, boxes #5 and #6 in Table are used for these simulations. WMetaD simulations are also performed with boxes #4 and #7 to study the effects of box size on the association constant. These simulations are conducted using the PLUMED package together with the CP2K code [44]. Association constants are obtained from the free energy surface (FES) using the method described by Chialvo et al. [45]. More details of this method are provided in the SI. The integration cutoff of the radial distribution function, r_c in Equation S11 is taken as half of the edge length of the respective simulation boxes, i.e. ~ 6.10 -6.30 Å for boxes #5 and #6 and ~ 10.00 -10.80 Å for boxes #4 and #7 (see Table 2). r_i in the same equation is set to ~ 2.8 Å in all biased simulations corresponding to the distance of the first minimum in FES.

55 3. Results

3.1. PIM parameters

The ionic polarizability values of the La³⁺ and Cl⁻ ions obtained from the DFT simulations are listed in Table 3. These values agree well with previously calculated polarizability values for these ions [30, 46, 47]. The other PIM parameters obtained with the methods described above are given in Table 4. The MSEs obtained for forces and dipole moments of the different subsystems are listed in Table S3. Plots comparing fitted and computed dipole moments and forces for different subsystems are shown in Figures S3-S8.

163 3.2. Speciation and structure

To test the performance of the new PIM potential, we first compare structural data from PIM and AIMD simulations using the boxes used as training sets. The calculated bond lengths and

coordination numbers from the PIM agree well with the AIMD data as shown in Table 5. For La-Cl, the AIMD data from Guan et al. [9] are used as a reference. Note that the latter study was performed with a different DFT exchange-correlation functional.

Table 5: Comparison of bond lengths and coordination numbers from PIM and AIMD simulations at 773 K and 5 kbar.

ion pair	box	bond length from	bond length from	CN from PIM	CN from
		PIM (Å)	AIMD (Å)		AIMD
La-O	#2	2.52	2.55	8.0	8.5(5)
Cl-O	#3	3.18	3.08	10.5(5)	10.5(5)
La-Cl	#5	2.85	2.78 [9]	1.5(5)	2.0 [9]

Next, La-Cl radial distribution functions, $g_{LaCl}(r)$, from PIM, N-POL and AIMD are compared in Figure 1. While the PIM data reproduce the AIMD results reasonably well, N-POL MD predicts strong La-Cl attraction that allows only negligible ion exchange throughout the simulation. This point is illustrated and discussed in greater detail later. La-O and Cl-O pair correlation functions from AIMD and PIM are shown in Figure S9. Both models predict similar sizes and overall structures of the hydration shells.

169

170

171

172

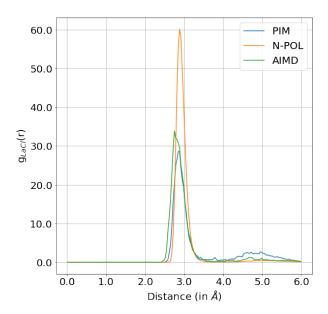

Figure 1: Comparison of the radial distribution functions $g_{LaCl}(r)$ obtained from PIM, N-POL and AIMD at 773 K and 5 kbar.

The predictions of ion pair distances and coordination numbers from PIM and N-POL MD at 175 both conditions are listed in Table 6 and compared to AIMD data. $g_{LaCl}(r)$ and $g_{LaO}(r)$ obtained at 176 773 K and 473 K from box #4 with both the models are shown in Figures S10 and S11 respectively. 177 For both conditions, N-POL predicts longer La-Cl and La-O distances as compared to PIM. 178 The number of nearest neighbors of the La^{3+} ion is ~ 7 for PIM, while it is ~ 8 for N-POL MD at 179 supercritical conditions. At subcritical conditions, the total CN is ~ 8 for PIM, while it is ~ 9 for 180 N-POL MD. In contrast to PIM, N-POL MD shows almost no La-Cl dissociation, resulting in high 181 CN at both conditions. This is reflected by sharp high peaks in $g_{LaCl}(r)$ at $\sim 2.8 \,\text{Å}$ in Figures S10 182 and S11 (left). At 473 K, PIM predicts an almost completely hydrated $\mathrm{La^{3+}}$ ion with ~ 8 water 183 molecules in the first hydration shell. This is seen in Figure S11 (left) where $q_{LaCl}(r)$ from PIM is 184 characterized by a narrow low peak at ~ 2.8 Å and a broad peak at ~ 5.0 Å. These two peaks indicate 185 the formation of two different types of ion pairs, contact ion pairs (CIPs) and solvent-shared ion 186 pairs (SShIPs). 187

3.3. Association constants

189

191

192

193

194

198

200

201

202

203

Reaction constants and energy barriers from the metadynamics simulations using WMetaD associated with different La-Cl association reactions are presented in Table 7. PMF data from Guan et al. [9] is used to recalculate $\log K_{eq}^{\infty}$ for the AIMD reference in Table 7 using the method described in the SI. Making these corrections leads to a maximum difference of about one log unit in $\log K_{eq}^{\infty}$ of the studied reactions. To make a credible comparison, PIM association constants obtained from the small simulation boxes are compared with the AIMD data. The effects of box size are discussed subsequently. La-Cl complexes show step-wise association reactions as

$$LaCl_{n-1}^{4-n} + Cl^{-} \longrightarrow LaCl_{n}^{3-n}$$
(10)

The reactions for successive values of n starting from n = 1 in Equation 10 are referred to as reactions 1, 2 and 3 respectively in the remaining paper.

Energy barriers for dissociation are approximated by ΔG between the first energy maximum and the first energy minimum in the FES, whereas relative stabilities of different metastable states are determined as free energy differences between them as shown in Figure 2 (right). It is to be noted that since the MD simulations are performed in the NVT ensemble, the free energies obtained with the biased simulations are the Helmholtz free energies. However, as shown in Schulze et al. [48], the change in volume due to the addition of an associated ion pair or a dissociated ion pair is negligibly

small at solvent density of $\sim 0.8 \,\mathrm{g/cm^3}$. These effects can therefore be neglected and the Helmholtz free energies can be considered to be approximately equal to the Gibbs free energies.

WMetaD is performed with the La-Cl interionic distance of the dissociating Cl⁻ as the collective variable (CV). The other Cl⁻ ligands are prevented from dissociating or associating by restraining them to a fixed distance either close to or far away from the La³⁺ ion. For example, in case of reaction 2, one Cl⁻ ligand is restrained at ~ 3 Å, the other is allowed to associate while the third one (to be associated in the next step) is restrained at $\sim 8-10$ Å. This is illustrated in Figure 2 (left, inset). In dilute solutions ions generally exist in equilibrium as contact ion pairs (CIPs - ion pairs where anion and cation are in close contact), solvent-shared ion pairs (SShIPs - ion pairs where anion and cation share hydration water molecules) and solvent-separated ion pairs (SSIPs - ion pairs where anion and cation form their individual hydration shells) as shown in Figure 3. These can be

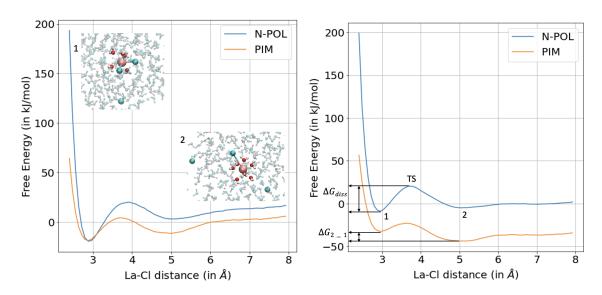

Figure 2: Left: FES of the $LaCl^{2+} + Cl^{-} \longrightarrow LaCl_{2}^{+}$ reaction at 773 K. Inset 1 shows the associated state where two Cl^{-} ions (green) are coordinated to the La^{3+} ion (brown) while the third Cl^{-} is restrained at a long distance. Inset 2 shows the dissociated state where one of the previously coordinating Cl^{-} ions is at a long distance. Right: FES of the $LaCl^{2+} + Cl^{-} \longrightarrow LaCl_{2}^{+}$ reaction at 473 K. ΔG_{diss} is the energy barrier for dissociation calculated as the difference in free energy between state 1 (associated state) and the high energy transition state (TS). ΔG_{2-1} is the energy difference between states 2 and 1.

distinguished from each other using the La-Cl interionic distance, thereby allowing proper sampling of all the metastable states.

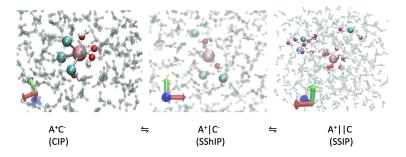

Figure 3: Different ion pairs obtained from simulations. Brown and green balls represent La³⁺ and Cl⁻ ions. In case of ClPs and SSIPs, red balls represent hydration water molecules of La³⁺, and magenta balls represent hydration water molecules of Cl⁻ ions. For SShIPs red balls are the shared hydration water molecules.

Figure 2 shows the FES of reaction 2 obtained from PIM and N-POL MD at supercritical and subcritical conditions. FES for the other reactions are shown in Figures S12 and S13. All FES primarily show two metastable states indicated by energy minima at ~ 3 Å and at ~ 5 Å (marked by 1 and 2 in Figure 2 right). State 1 is attributed to the CIPs whereas state 2 is populated by SShIPs and these metastable states are separated by a high-energy transition state (TS). Relative stabilities of CIPs and SShIPs show a change from subcritical to supercritical conditions with PIM. However, no such change in relative stability is observed with N-POL MD. ΔG_{2-1} obtained from the different models at 773 K and 473 K is shown in Figure S14.

In Table 7, high values of the energy barrier for dissociation can be seen compared to the thermal energy, k_B T. This creates a kinetic bottleneck in unbiased simulations, which underlines the motivation to use WMetaD for this system. Further, it can be inferred that PIM predicts lower energy barriers for dissociation compared to those from N-POL MD for all reactions at subcritical as well as supercritical conditions. PIM predicts increasing energy barriers for successive dissociation reactions at both conditions. N-POL MD predicts almost constant energy barriers at 773 K. At 473 K, an increase in energy barrier from reaction 1 to 2 followed by a decrease in reaction 3 is observed.

Both models predict positive values of $\log K_{eq}^{\infty}$ for all the stepwise association reactions due to the tendency of ions to associate in water at high temperatures. In general, the calculated values of $\log K_{eq}^{\infty}$ for PIM are lower than those for N-POL MD for all association reactions at subcritical and supercritical conditions. This is because of the deep energy basins predicted by N-POL MD for CIPs, which make them more exothermic than those from PIM. Both models show an increase in $\log K_{eq}^{\infty}$

Table 7: Energy barriers and reaction constants of La-Cl association reactions from different models at supercritical conditions (773 K, 5 kbar) and subcritical conditions (473 K, 400 bar).

with increasing temperature. Note that FES and $\log K_{eq}^{\infty}$ have a many-to-one relation, which means

4. Discussion

4.1. Speciation and structure: Comparison with available AIMD and experimental data

The new PIM potential predicts La-Cl bond distances closer to AIMD data compared to N-POL

MD (Table 6) at both conditions studied here. However, distances from both PIM and N-POL MD

that the same $\log K_{eq}^{\infty}$ value can be obtained from different FES. Therefore, an accurate prediction

of the underlying FES is of paramount importance to retrieve reliable association constants.

are shorter than the 2.90-3.02 Å range predicted by experiments at similar conditions [9]. Shorter 244 bond lengths from PIM are a consequence of shorter bond lengths predicted by DFT which is used 245 to generate the training configurations. Both models predict a decrease in La-Cl bond length with 246 increasing temperature, which is consistent with experiments [9] and AIMD [9] at similar conditions. 247 N-POL MD simulations with box #4 at both conditions show almost no La-Cl dissociation resulting 248 in CN > 2. The presence of high-energy barriers for dissociation ($\sim 7 k_B T$, Table 7) at both conditions 249 is the reason why La-Cl dissociation is kinetically unfavorable in N-POL MD. Similar conclusions 250 were drawn by Zhang and Yan [49] with a different set of pair potentials at similar temperature 251 conditions. As the existing N-POL potentials were optimized to reproduce structures at ambient conditions, we attempted to refit the LJ potential from Migliorati et al. [12] with atomic force 253 data at supercritical conditions. However, this refitted potential also predicted unfavourable La-Cl 254 dissociation. The observed inability of LJ-type potentials to predict the hydration free energies and 255 ion-oxygen distances of divalent cations was already addressed by Li et al. [50], who attributed this 256 behavior to the lack of ion-dipole interactions. These problems are overcome with PIM, which softens 257 the La-Cl interactions resulting in significant dissociation at both conditions, consistent with AIMD 258 simulations and extended X-ray absorption fine structure (EXAFS) data [9] at similar conditions. 259 At 473 K, ΔG_{2-1} is negative for PIM reactions (Figure S14), which means that SShIP is the more 260 stable state compared to CIP. This is also seen in the unbiased simulations (PIM with box #4, Table 261 6) where almost all Cl⁻ ligands preferentially populate the second coordination shell at a distance 262 of \sim 5 Å. La-O distances from PIM are shorter compared to those from EXAFS data [9] at similar 263 conditions. 264

Figure 4 shows a comparison of the total number of ligands and the number of Cl⁻ ligands in 265 the first coordination shell. With increasing temperature, the static dielectric constant of water 266 decreases, which promotes ion association. This effect is seen in PIM where an increase of about one Cl⁻ ion is observed from subcritical to supercritical conditions, consistent with AIMD data 268 [9], EXAFS studies [9], XAS studies [23] and HKF model data [6]. N-POL MD predicts higher 269 Cl⁻ coordination and negligible change with temperature. In terms of the absolute number of Cl⁻ 270 ligands, the PIM data agrees well with the HKF model [6] generated using solubility data from 271 Migdisov et al. [24] and EXAFS data [9], whereas an overestimation of about one ligand is observed 272 for N-POL MD. With decreasing temperature, PIM shows an increase in the total number of ligands 273 of about one, in agreement with EXAFS data [9]. XAS data [23] predict an increase of about 274 three ligands. However, XAS generally overestimates coordination numbers indicated by the 10-fold 275

coordinated La³⁺ predicted at subcritical conditions [23]. N-POL MD predicts negligible change in
the total number of ligands with temperature. In terms of the absolute number of ligands in the
first coordination shell, PIM data agree well with EXAFS [9] and AIMD [9] data, while N-POL MD
overestimates the number of ligands by about one. PIM also shows better agreement with XAS
studies [23] in terms of the total number of ligands compared to N-POL MD at 773 K. In general,
La-O distances predicted by PIM are shorter than those in AIMD and experiments [9] at similar
conditions.

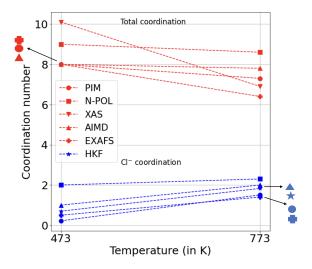

Figure 4: Comparison of coordination numbers from PIM, N-POL MD with XAS [23], EXAFS [9], AIMD [9] and HKF model [6] data

4.2. Ion association thermodynamics: Comparison with available AIMD and experimental data.

In general, association constants predicted by AIMD, N-POL MD and PIM follow the order, $\log K_{eq,N-POL}^{\infty} > \log K_{eq,PIM}^{\infty} > \log K_{eq,AIMD}^{\infty}$. This is seen in Table 7 and also illustrated in Figure S15. Although PIM gives better $\log K_{eq}^{\infty}$ values as compared to N-POL, the disagreement with AIMD is still relatively large, i.e. about one log unit in some cases. Table 8 shows the cumulative association constants, $\log \beta$ obtained from N-POL MD, PIM, AIMD [9] and the HKF model parameterized with solubility data from Migdisov et al. [24] up to ~350 °C. They are obtained by cumulative addition of $\log K_{eq}^{\infty}$ values shown in Table 7 and, hence, follow the same descending order as association constants. $\log \beta$ predicted by PIM for reactions 2 and 3 at 473 K are in better agreement with the thermodynamic model and AIMD than N-POL MD. Both models predict an increase in $\log \beta$ values of LaCl²⁺ and LaCl⁺ with increasing temperature, in agreement with data from the HKF model

285

287

288

290

292

293

up to ~ 400 °C [24] and with AIMD data [9]. Due to the increased stability of La-Cl complexes at higher temperatures, the stepwise addition of Cl⁻ into the coordination sphere of La³⁺ becomes more exothermic at higher temperatures.

Table 8: Cumulative association constants $\log \beta$ obtained from different models (*values are from two the data sets shown in Migdisov et al. [24])

temperature	reaction	method	$\log \beta$
773 K	$La^{3+} + Cl^{-} \longrightarrow LaCl^{2+}$	PIM	2.86
		N-POL MD	3.51
		AIMD [9]	2.72
	$\text{La}^{3+} + 2 \text{Cl}^{-} \longrightarrow \text{LaCl}_{2}^{+}$	PIM	5.06
		N-POL MD	6.15
		AIMD [9]	4.38
	$\operatorname{La}^{3+} + 3\operatorname{Cl}^{-} \longrightarrow \operatorname{LaCl}_{3}$	PIM	6.59
		N-POL MD	7.92
		AIMD [9]	4.91
473 K	$\operatorname{La}^{3+} + \operatorname{Cl}^{-} \longrightarrow \operatorname{LaCl}^{2+}$	PIM	2.29
		N-POL MD	2.45
		AIMD [9]	1.81
		Model [24]	2.29, 2.38*
	$\text{La}^{3+} + 2 \text{Cl}^{-} \longrightarrow \text{LaCl}_{2}^{+}$	PIM	3.89
		N-POL MD	4.05
		AIMD [9]	3.00
		Model [24]	3.86
	$La^{3+} + 3Cl^{-} \longrightarrow LaCl_{3}$	PIM	4.86
		N-POL MD	4.81
		AIMD [9]	3.18

The relative stabilities of the metastable CIPs and SShIPs predicted by PIM are in agreement with AIMD data as shown in Figure S14. Both predict CIPs as the more stable state at 773 K and SShIPs as the more stable state at 473 K in contrast to N-POL MD that always predicts CIPs as the more stable state at both conditions. Zhang and Yan [49] also predict similar trends of energy barrier and relative stabilities with a different set of non-polarizable pair potential at similar temperature

297

298

299

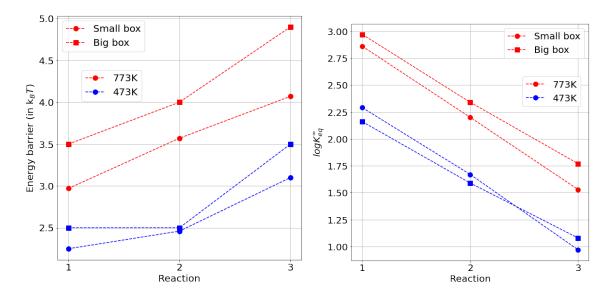

Figure 5: Comparison of energy barriers (left) and $\log K_{eq}^{\infty}$ of association reactions (right) from small and big simulation boxes. Integration limits of \sim 6.30 Å and \sim 11 Å were used for small and big boxes, respectively.

conditions. Absolute values of ΔG_{2-1} from PIM are generally lower than those from AIMD.

From Table 8, it may seem that PIM and N-POL MD are more accurate than AIMD in predicting formation constants. However, we do not draw such conclusions here because formation constants are derived from the corresponding reaction FES. As discussed above, FES from N-POL MD are unable to predict the relative stabilities of the different metastable states correctly. We do not have any data to prove that FES from PIM are more accurate than their AIMD counterparts.

4.2.1. Effect of box size on association constant

MD simulations use periodic boundary conditions to replicate bulk liquid systems. The success of this assumption depends on the size of the simulation box which determines the distance between the particles and their nearest images. A small simulation box would mean smaller distances between particles and their periodic images leading to higher interactions between them, which is not desirable as this imposes correlations not expected in fluids. To understand the effect of box size on the calculated values of $\log K_{eq}^{\infty}$ and energy barriers, WMetaD simulations were performed with boxes #4 and #7 in Table 2 with the new PIM potential. The results are presented in Figure 5.

Figure 5 shows minor disagreements (maximum difference of $\sim 0.9 \,\mathrm{k}_B T$ in energy barriers and $\sim 0.25 \,\mathrm{log}$ units in association constants) between results from the two simulation boxes. The technique used to calculate the association constants in this work boils down to calculating $g^{\infty}(r)$, which

is the radial distribution function in the limit of infinite dilution. For highly dilute solutions, ob-319 taining $g^{\infty}(r)$ from MD simulations is difficult as sampling deficiency occurs due to rather short 320 simulation times, leading to poor statistics. Therefore, the more practical way is to calculate $q^{\infty}(r)$ 321 from ΔG obtained from biased simulations using Equation S12. If it were possible to simulate a 'theoretically' infinitely dilute solution (the simulation box is big enough with adequate number of 323 water molecules and La, Cl particles to reach bulk behavior), $g^{\infty}(r)$ would converge to 1 and hence 324 $\phi(r)$ would converge to 0 at $r \to \infty$, which is the dissociated state in the ideal case. However, due 325 to extreme long-range nature of Coulomb interactions and limited number of La, Cl particles, this is 326 difficult to achieve even in simulation boxes with edge lengths of ~30 Å [51]. Hence, the dissociated state is taken to be the limiting continuum behavior where charged particles interact via screened 328 Coulomb interaction given by $\phi_{analytical}(r) = -q^2/4\pi\epsilon_0\epsilon_r r$. FES obtained from simulation boxes 329 of different sizes are rigidly shifted so that their tails coincide with the analytical solution at long 330 distances, as shown in Figure 6. The difference in the $\log K_{eq}^{\infty}$ values arise due to the difference in 331 length of the tail coinciding with the analytical solution. However, once the FES is properly aligned to the analytical solution (indicating efficient sampling of all the metastable states), dependence of 333 $\log K_{eq}^{\infty}$ on cutoff distance is weak beyond $\sim 5\,\text{Å}$ (corresponding to SShIP) at high temperatures, as 334 shown in Figure S16. Therefore, results obtained from small simulation boxes used in AIMD sim-335 ulations are acceptable at these conditions. The effect of box size may become important at lower 336 temperatures where SSIPs are stabilized in addition to CIPs and SShIPs. Since SSIPs are formed at ~ 7.5 Å-8 Å efficient sampling of these ion pairs is no longer possible in small simulation boxes. 338 Bigger simulation boxes with minimum edge lengths of $\sim 16-17 \,\text{Å}$ are required to calculate reliable 339 association constants at lower temperatures.

5. Conclusion

345

347

We fit a new polarizable potential for La³⁺ in Cl⁻-bearing hydrothermal systems from firstprinciples AIMD simulations. Production simulations were performed at 773 K and 473 K to derive structural and thermodynamic properties of La³⁺ in dilute to concentrated solutions.

The new PIM interaction potential gives good estimates of La-Cl and La-O distances at the studied conditions. PIM provides better estimates of total coordination and Cl⁻ coordination numbers compared to N-POL MD in dilute solutions. It also reproduces the increase in La-Cl coordination with increasing temperature as observed in experiments. However, the La-O distances predicted by PIM are shorter than the experimental data at similar conditions.

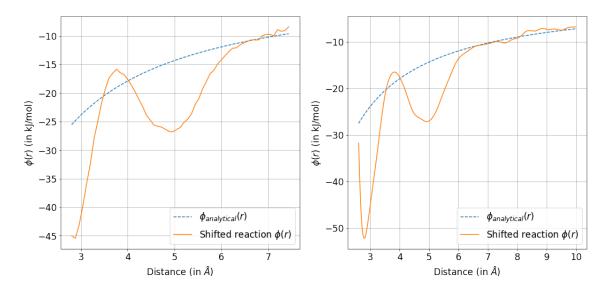

Figure 6: $\phi(r)$ obtained from small simulation box (left) and big simulation box (right) aligned to the analytical solution at 773 K, 5 kbar. $\phi(r)$ from larger box shows a longer tail coinciding with the analytical solution.

Calculation of association constants reveal increasing stability of LaCl²⁺ and LaCl⁺ complexes with increasing temperature. In general, the formation constants calculated from PIM simulations are closer to the data from the AIMD and HKF models than those from N-POL MD. This is despite the fact that no energy values are used in fitting the PIM. Relative stabilities of CIPs and SShIPs predicted by PIM are in agreement with AIMD at both conditions. Altogether, the newly fitted PIM gives more precise structural and thermodynamic insight into dilute La-Cl-bearing hydrothermal fluids at both the studied temperature and pressure conditions than those from simple pair potentials, with reasonable computational cost. We also show that the effects of simulation box size on calculated thermodynamics properties are negligibly small at high temperatures. Our results underpin the importance of an explicit description of ionic polarizability to retrieve reliable structural and thermodynamic information in hydrothermal systems containing highly polarizable anions such as Cl⁻ and cations with high polarization power such as La³⁺.
